Measurement Models for Other Kinds of Continuous but Non-Normal Outcomes in Mplus version 7.4

This example examines alternative factor models for 6 outcomes that measure use of controlled substances on a scale of 0 to 6, where: 0 = Never used, 1 = Have used once or twice, 2 = Once or twice a year, 3 = Less than once a month, 4 = Once or twice a month, 5 = Once or twice a week, and 6 = Daily. Below are the distributions of the outcomes in a sample of 356 rural adolescents. It is admittedly not the best example because of the constrained 7-point ordinal scale rather than a true count, but it is what I have to illustrate these models...

Assuming we wish to model the distribution as some kind of continuum (i.e., not as graded response), there are several reasonable options described below for factor models that assume different conditional item response distributions. We will see examples of how to specify each of these in Mplus next, using MLR (robust ML) for all models. Model fit statistics will only be available for normal models that are easily summarized by a covariance matrix, though.

Normal (regular CFA) Model: We fit a linear model of the factor predicting the ORIGINAL item response and assume each item follows a conditionally normal distribution (i.e., the item residuals are normally distributed after controlling for the factor). The measurement model would thus include per item an intercept (the expected item response when factor = 0), a factor loading (change in item response per unit change in the factor), and a residual variance (amount of item variance not predicted by the factor). A normal model that assumes a linear relationship between the item response and the factor (i.e., an interval scaling of the response options) is not likely to be tenable for these kinds of data, but it's the most common approach. Although we can use MLR instead of ML for CFA models when item response distributions look non-normal to correct the fit statistics and standard errors accordingly, that doesn't solve the basic problem of whether it is reasonable to expect a linear relationship between the item response and the factor. The alternative models below address this latter problem.

Poisson and Negative Binomial Models: We fit a linear model of the factor predicting the LOG of the item response. We assume the items follow a Poisson distribution in which the mean is the same as the variance (a single parameter called "k"). The Poisson measurement model would thus include per item an intercept (the expected LOG of the item response when factor = 0) and a factor loading (change in the LOG of the item response per unit change in the factor), but no estimated residual variance (because it is determined by the conditional mean). In the closely related **Negative Binominal** model, we add to the Poisson model a scaling factor " α " that allows the residual variance to exceed the mean (called "over-dispersion"), such that the new variance = k(1+k α). In Mplus we can test if the scaling factor is different than 0 (because 0=Poisson), and thus we could do a nested model comparison as to whether a Negative Binominal fits better than a Poisson for each item response. These models works well for integer count data that can't be negative or data that are skewed, but they run into problems if the over-dispersion is caused by an excess of zeros. The alternative models below address this extra-zero problem.

Zero-Inflated Poisson (ZIP) or Zero-Inflated Negative Binomial (ZINB): These models specify two underlying distributions in the observed item responses: "structural zeros" and "non-structural zeros" (includes expected zeros based on regular Poisson or negative binomial distributions). A structural zero would never do any of the behaviors in question, whereas an expected zero (who belongs in the regular distribution) might do the general behavior, just not that particular item (e.g., zero for use of speed but non-zero for use of weed). We can potentially fit a factor model to each part of the distribution. The structural zero measurement model would have a linear model of the factor predicting the LOGIT of being a structural zero (so the "higher category" being predicted is the structural zero as 1). The structural zero factor model would thus estimate thresholds (expected LOGIT of being a non-structural zero if the factor = 0) and factor loadings (change in the LOGIT of being a structural zero per unit change in the factor). The non-structural-zero measurement model would have a linear model of its factor predicting the LOG of the item response, and the ZINB would again have an added scaling parameter for over-dispersion. Thus the non-structural-zero measurement model would estimate intercepts (expected LOG of item response if factor = 0) and factor loadings (change in LOG of item response per unit change in factor). Just as the Poisson is nested within the Negative Binomial (tests if the scaling parameter for extra residual variance is needed), the ZIP is nested within the ZINB. In addition, the AIC and BIC can be compared between the Poisson and ZIP, or between the Negative Binomial and ZINB, to see if the zero-inflation parameters are helpful. It is not required to have a factor for the inflation, but one can do so in Mplus (very hard to estimate). However, the interpretation of two kinds of zeros can be confusing, and so the alternative models below address the issue of excess zeros more directly.

Negative Binomial Hurdle and Two-Part Models: Rather than trying to distinguish "structural zeros" from "non-structural zeros", these models simply split each observed item response into two new variables: "0 vs. something", and "how much if not 0". The models differ in how they accomplish this same idea. The negative binomial hurdle model for "0 vs. something" uses "0" as what is predicted. Thus, the measurement model for the "not 0 vs. 0" part would have a linear model of its factor predicting the LOGIT of being a 0. It thus estimates a threshold (expected LOGIT of not being 0 if factor = 0) and a factor loading (expected change in the LOGIT of being a 0 per unit change in the factor). The negative binomial hurdle measurement model for the "not 0" part would have a linear model of its factor predicting the LOG of the item response past 0 (a zero-truncated distribution). It thus estimates an intercept (expected LOG of the non-zero item response if factor = 0), a factor loading (expected change in the LOG of the non-zero item response per unit change in the factor), and a scaling parameter for the over-dispersion of the residual variance. The two-part model for the "0 vs. something" uses "something" as what is predicted. Thus, the measurement model for the "0 vs. not 0" part would have a linear model of its factor predicting the LOGIT of being not 0. It thus estimates a threshold (expected LOGIT of being 0 if factor = 0) and a factor loading (expected change in the LOGIT of being not 0 per unit change in the factor). The two-part measurement model for the "not 0" part would have a linear model of its factor predicting the LOG of the item response past 0. It thus estimates an intercept (expected LOG of the non-zero item response per unit change in the factor), and a residual variance. The "not 0" model uses a LOG transformation by default, but other transformations (including none) are available as well.

Here is one alternative: (1) Normal CFA model with Robust ML

                                                                                                          0.094
                                                                                                                    5.892
                                                                                                                                0.000
the zero-inflation part (the logit of being a structural zero is
predicted by each factor), those models showed severe convergence
                                                                        Variances
problems, most likely because the probability of being a structural
                                                                            RECAMT
                                                                                               1.000
                                                                                                          0.000
                                                                                                                   999.000
                                                                                                                              999.000
zero was so small in this particular sample. For instance, the largest
                                                                            DRUGAMT
                                                                                               1.000
                                                                                                          0.000
                                                                                                                   999.000
                                                                                                                              999.000
probability is for the mean of CIG#1 (logit of -2.597 = \text{prob of } .07).
                                                                         Dispersion - ALPHA MULTIPLIER TO INCREASE VARIANCE RELATIVE TO MEAN
So we proceed with a single factor for each item for now.
                                                                                               0.101
                                                                                                          0.093
                                                                                                                     1.091
                                                                                                                                0.275
                                                                            CTG
Further, the AIC and BIC are higher in this zero-inflated model,
suggesting that most of the items do not need "structural zeros", or
that including inflation parameters for the extra zeros does not help
model fit.
```

Here is another alternative: (4) Two-Part Factor Model (here, with a log transformation of the continuous part)

Unfortunately, absolute model fit statistics are not given for the non-normal models, and relative fit statistics (AIC and BIC) are not comparable across the normal, Poisson/NB/ZIP/ZINB, and two-part families. What we can do is examine the predicted item response across factor levels for each alternative model and see what seems reasonable. Here are the plots (made in excel) for cigarettes and for weed, with scale ends noted with the horizontal lines.

As we can see, the Negative Binomial (for cigarettes) and Poisson (for weed) dramatically overshoot the possible item response at higher levels of the factor. The same is true for the zero-inflated versions of these models. But the normal model extends below the possible scale for both items.

The two-part models seems to have the best fit – results are shown for models with either a log transformation (model 4) or no transformation of the "how much" part (those model results were not shown). They both "shut off" towards the 0 end of the scale as needed (because "0 vs. something" is covered by the other part not plotted), but the predicted "how much" doesn't have the dramatic upswing at higher factor levels like the other models. Plus they have a more straightforward interpretation than the inflated models: Here, this is the relationship between answering "how much if not 0" and the factor.

Not shown is the model for the other factor that predicts the probability of "0 vs. something" instead. Finally, we could have had the binary "0 vs. something" items and the "how much if not 0" items load onto the same factor (but fit got worse for that in these data).
